# Proton-powered subunit rotation in single membrane-bound $F_0F_1$ -ATP synthase

Manuel Diez<sup>1</sup>, Boris Zimmermann<sup>1</sup>, Michael Börsch<sup>2</sup>, Marcelle König<sup>3</sup>, Enno Schweinberger<sup>3</sup>, Stefan Steigmüller<sup>1</sup>, Rolf Reuter<sup>1</sup>, Suren Felekyan<sup>3</sup>, Volodymyr Kudryavtsev<sup>3</sup>, Claus A M Seidel<sup>3</sup> & Peter Gräber<sup>1</sup>

Synthesis of ATP from ADP and phosphate, catalyzed by  $F_0F_1$ -ATP synthases, is the most abundant physiological reaction in almost any cell.  $F_0F_1$ -ATP synthases are membrane-bound enzymes that use the energy derived from an electrochemical proton gradient for ATP formation. We incorporated double-labeled  $F_0F_1$ -ATP synthases from *Escherichia coli* into liposomes and measured single-molecule fluorescence resonance energy transfer (FRET) during ATP synthesis and hydrolysis. The  $\gamma$  subunit rotates stepwise during proton transport-powered ATP synthesis, showing three distinct distances to the b subunits in repeating sequences. The average durations of these steps correspond to catalytic turnover times upon ATP synthesis as well as ATP hydrolysis. The direction of rotation during ATP synthesis is opposite to that of ATP hydrolysis.

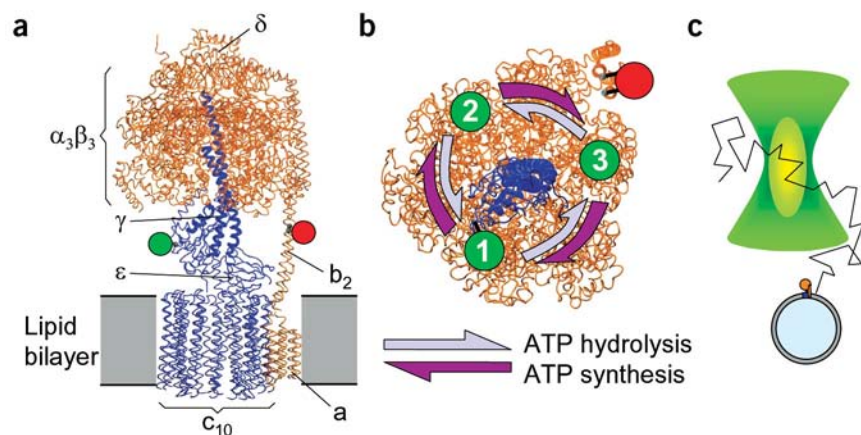

To clarify the central role of energy transduction and the rotary mechanism of  $F_0F_1$ -ATP synthase, much experimental work has focused on the mechanistic events in this molecular motor<sup>1–17</sup>.  $F_0F_1$ -ATP synthase catalyzes the formation of ATP from ADP and phosphate in bacteria, mitochondria and chloroplasts, and this reaction is driven by conversion of Gibbs free energy derived from a transmembrane electrochemical proton gradient<sup>1</sup>. The enzyme consists of two parts,  $F_1$  and  $F_0$ , which in *E. coli* have the subunit composition  $\alpha_3\beta_3\gamma\delta\epsilon$  and  $ab_2c_n$  with an expected number  $n$  of  $c$  subunits between 10 and 12, respectively (Fig. 1a). ATP synthesis takes place at the three  $\beta$  subunits of  $F_1$ , which sequentially adopt different conformations during catalysis<sup>2</sup>. Due to different interactions of each  $\beta$  subunit with the  $\gamma$  subunit, three possible conformations of the catalytic binding sites are found in the X-ray structure<sup>3</sup>. A sequential conversion of the conformations of the catalytic sites is caused by rotation of the  $\gamma$  subunit, which is located in the center of the  $\alpha_3\beta_3$  complex. Rotation of the  $\gamma$  subunit is assumed to be coupled mechanically to proton translocation by a rotational movement of the  $c$ -ring<sup>4</sup> of  $F_0$ . Therefore, the subunits are also defined as ‘rotor’ ( $\gamma\epsilon c_n$ , Fig. 1) and ‘stator’ ( $\alpha_3\beta_3\delta ab_2$ , Fig. 1)<sup>5–8</sup>.

In single immobilized  $F_1$  subcomplexes, subunit rotation during ATP hydrolysis has been demonstrated by video-microscopic experiment using a fluorescent actin filament connected to the  $\gamma$  subunit as a marker of its orientation<sup>9</sup>. Hydrolysis of ATP led to rotation of the  $\gamma$  subunit in 120° steps. Recently, resolution of substeps<sup>10,11</sup> has shown that the binding event of ATP at a relative  $\gamma$ -subunit position of 0° (or 120° and 240°, respectively) and the catalytic processes of ATP hydrolysis and product release at a relative  $\gamma$ -subunit position between 80° and 90° are associated with different angular

orientations of the  $\gamma$  subunit. The direction of rotation was counter-clockwise when viewed from  $F_0$  to  $F_1$  (Fig. 1b). Actin-filament attachment has also been used to show rotation of the  $c$  subunits of  $F_0$  using immobilized complexes<sup>12,13</sup>; and by a single-fluorophore polarization experiment<sup>14</sup>. ‘Molecular dynamics’ simulations of the direction of ATP synthesis showed induced conformational changes within  $F_1$  when an external rotary force was applied to the  $\gamma$  subunit<sup>15,16</sup>.

However, up to now the rotation of the central  $\gamma$  subunit during proton-powered ATP synthesis could only be demonstrated indirectly<sup>17</sup>. The following questions must be investigated: (i) can we observe a rotation of the  $\gamma$  subunit coupled to proton translocation during ATP synthesis, that is distinguishable from an oscillation mode between only two positions for the  $\gamma$  subunit? (ii) Is the direction of rotation during ATP synthesis opposite or identical to that during ATP hydrolysis; that is, is this enzyme a bidirectional or unidirectional motor? (iii) Is the movement of the  $\gamma$  subunit during proton translocation continuous or stepwise? Because consecutive conformational motions in protein machines are stochastic and thus can hardly be synchronized, the subunit movements in  $F_0F_1$ -ATP synthase must be studied at the single-molecule level. Here we present the use of intramolecular single-molecule FRET to observe the rotary movement of the  $\gamma$  subunit during proton-powered ATP synthesis by single  $F_0F_1$ -ATP synthase. The FRET donor was attached at the rotating  $\gamma$  subunit and the FRET acceptor crosslinked the non-rotating b-subunit dimer. During catalysis, fluctuating FRET efficiencies indicate the relative movement of the labels because their distances sequentially interchange as a result of the rotation of the  $\gamma$  subunit.

**Figure 1** Model of  $F_0F_1$  from *E. coli* (see Methods). (a) Side view. The FRET donor is bound to the  $\gamma$  subunit (green circle), the FRET acceptor Cy5bis to the b subunits (red circle). 'Rotor' subunits are blue, 'stator' subunits are orange. (b) Cross-section at the fluorophore level, viewed from  $F_0$ . Cy5bis (red) crosslinks the b subunits. Donor position 1 (green) of cysteine  $\gamma$ -T106C is farthest away from b-Q64C. Rotation of the  $\gamma$  subunit by  $120^\circ$  and  $240^\circ$  results in donor positions 2 and 3, respectively. (c) Photon bursts are observed when a freely diffusing single liposome with a single FRET-labeled  $F_0F_1$  traverses the confocal detection volume (yellowish) within the laser focus (green).

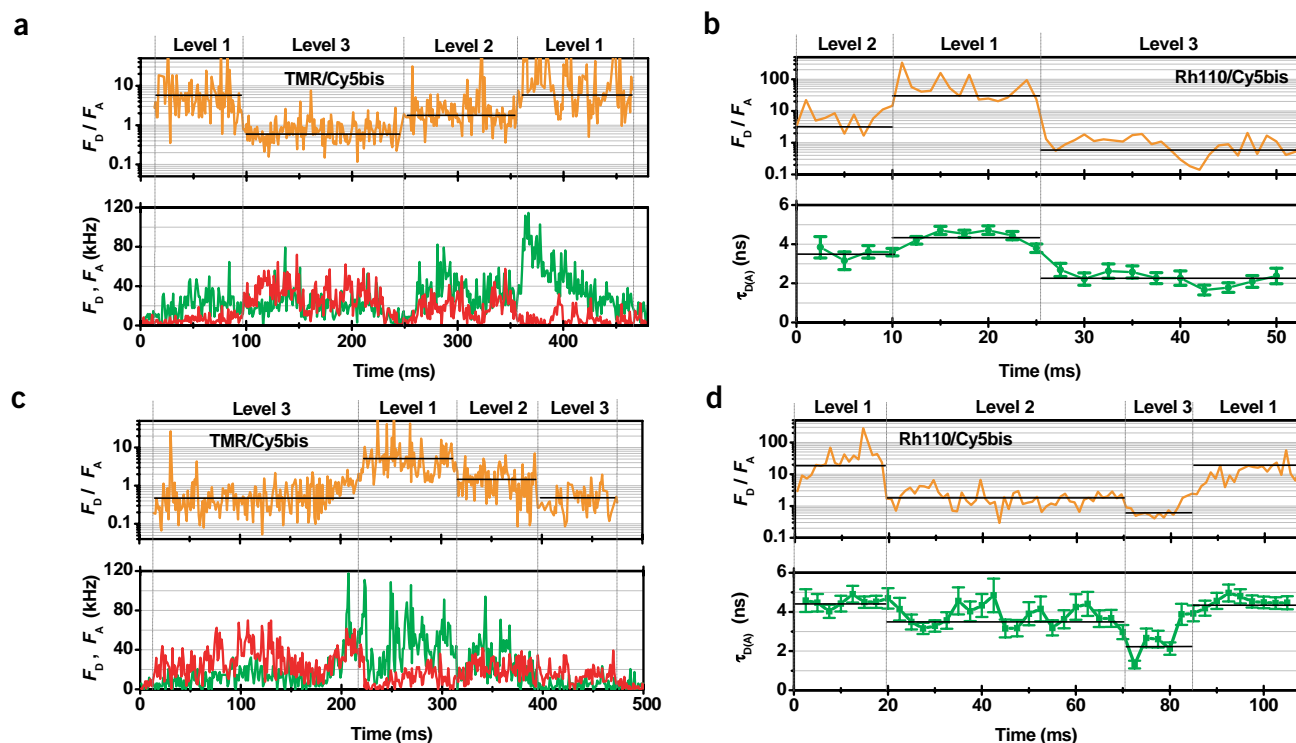

## RESULTS

Reconstituted  $F_0F_1$ -ATP synthase with FRET labels

To study intersubunit rotation of the membrane-bound  $F_0F_1$ -ATP synthase (referred to as  $F_0F_1$  below) from *E. coli* under conditions of ATP synthesis and hydrolysis, the following prerequisites must be met: (i) preparation of the fully functional holoenzyme  $F_0F_1$  in a quasi-native environment without additional immobilization; (ii) generation of a proton gradient across the lipid membrane; (iii) attachment of reporters for rotation that are small enough to allow undisturbed subunit movement during catalysis. We met these requirements by incorporating  $F_0F_1$  into a liposome and by specifically labeling the b-subunit dimer and the  $\gamma$  subunit with two

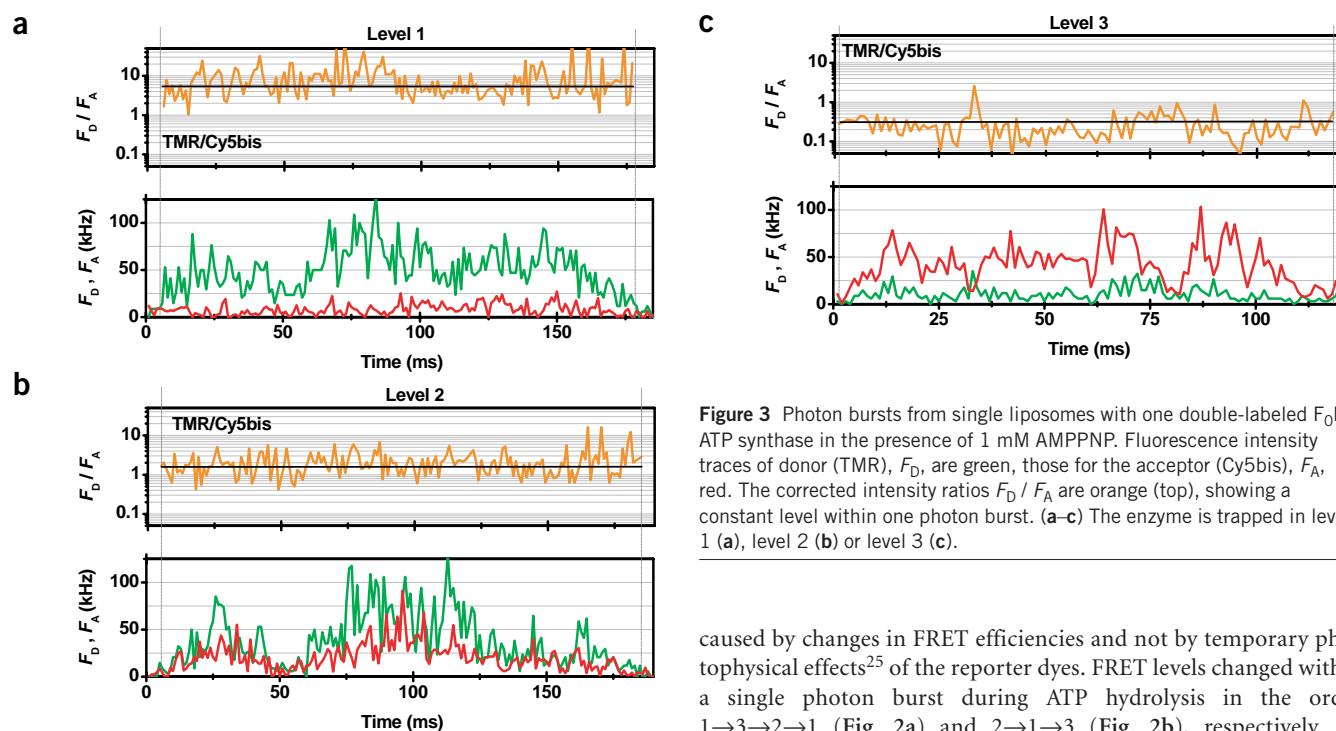

different fluorophores suitable for single-molecule FRET. To exclude specific photophysical effects of the dyes, we used two alternative FRET donor fluorophores, either tetramethylrhodamine-maleimide (TMR) or rhodamine110-maleimide (Rh110) bound to the  $\gamma$  subunit at residue 106 (Fig. 1a,b). The FRET acceptor, the bifunctional cyanine-5-bismaleimide (Cy5bis), crosslinked the two cysteines at position 64 in the b-subunit dimer of  $F_0F_1$ , avoiding ambiguity in the location of the dye<sup>18</sup>.

To avoid any perturbations from surfaces, the labeled holoenzyme was investigated in freely diffusing liposomes that proved to be fully functional. The catalytic rates of these double-labeled enzymes were  $\nu_S = (23 \pm 3) \text{ s}^{-1}$  for ATP synthesis and  $\nu_H = (67 \pm 6) \text{ s}^{-1}$  for ATP

**Figure 2** Photon bursts from single  $F_0F_1$ -ATP synthases in liposomes. (a,b) Photon bursts during ATP hydrolysis. (c,d) Photon bursts during ATP synthesis. FRET donor is TMR in a and c, Rh110 in b and d; FRET acceptor is Cy5bis in all traces. Fluorescence intensity traces of the donor,  $F_D$ , and acceptor,  $F_A$ , are green and red, respectively, in a and c (time window 1 ms). Corrected intensity ratios  $F_D / F_A$  are orange in all panels (time window 1 ms), and fluorescence lifetimes of the donor Rh110 are green in b and d (total time window 5 ms, shifted by 2.5 ms per data point). Three distinct FRET levels are attributed (1, 2 or 3) at top of panels. Black horizontal lines indicate the mean FRET levels from the distributions in Figure 4 (additional traces are shown in Supplementary Fig. 2 online).

**Figure 3** Photon bursts from single liposomes with one double-labeled  $F_0F_1$ -ATP synthase in the presence of 1 mM AMPPNP. Fluorescence intensity traces of donor (TMR),  $F_D$ , are green, those for the acceptor (Cy5bis),  $F_A$ , red. The corrected intensity ratios  $F_D / F_A$  are orange (top), showing a constant level within one photon burst. (a–c) The enzyme is trapped in level 1 (a), level 2 (b) or level 3 (c).

hydrolysis, both of which are similar to those of the unlabeled  $F_0F_1$ -ATP synthase<sup>19,20</sup>. Upon addition of 40  $\mu$ M of the inhibitor  $N,N'$ -dicyclohexylcarbodiimide (DCCD), ATP synthesis was reduced to  $v_S = (4 \pm 3) \text{ s}^{-1}$  and ATP hydrolysis to  $v_H = (2 \pm 2) \text{ s}^{-1}$ , confirming that catalysis was coupled to proton transport<sup>21,22</sup>.

### Stepwise $\gamma$ -subunit rotation during ATP hydrolysis

First, we analyzed rotary movements during ATP hydrolysis in the presence of 1 mM ATP. Using intramolecular single-molecule FRET<sup>18,23,24</sup> and single-molecule multiparameter fluorescence detection<sup>25</sup>, we obtained quantitative fluorescence information (intensity, lifetime and anisotropy in two spectral regions) from the attached reporters at high time resolution. Single FRET-labeled enzymes incorporated into liposomes were detected by their fluorescence photon bursts while traversing the confocal detection volume (Fig. 1c). Figure 2a shows a long-lasting photon burst with large fluctuations of the fluorescence intensities of donor,  $F_D$  (green) and acceptor,  $F_A$  (red). The ratio of corrected fluorescence intensities  $F_D / F_A$  was calculated (Fig. 2) to correlate these fluctuations with changes in the intramolecular FRET efficiency; that is, with distance changes between the two fluorophores. For the observed photon bursts, we found three different constant levels of  $F_D / F_A$  (levels 1, 2 and 3) corresponding to three distinct distances between the labels at the  $\gamma$  and b subunits. These FRET states interchanged in sudden jumps among the levels, with a transition time faster than the time resolution (binning time 1 ms). The burst in Figure 2a shows a sequence of four steps of the  $F_D / F_A$  levels.

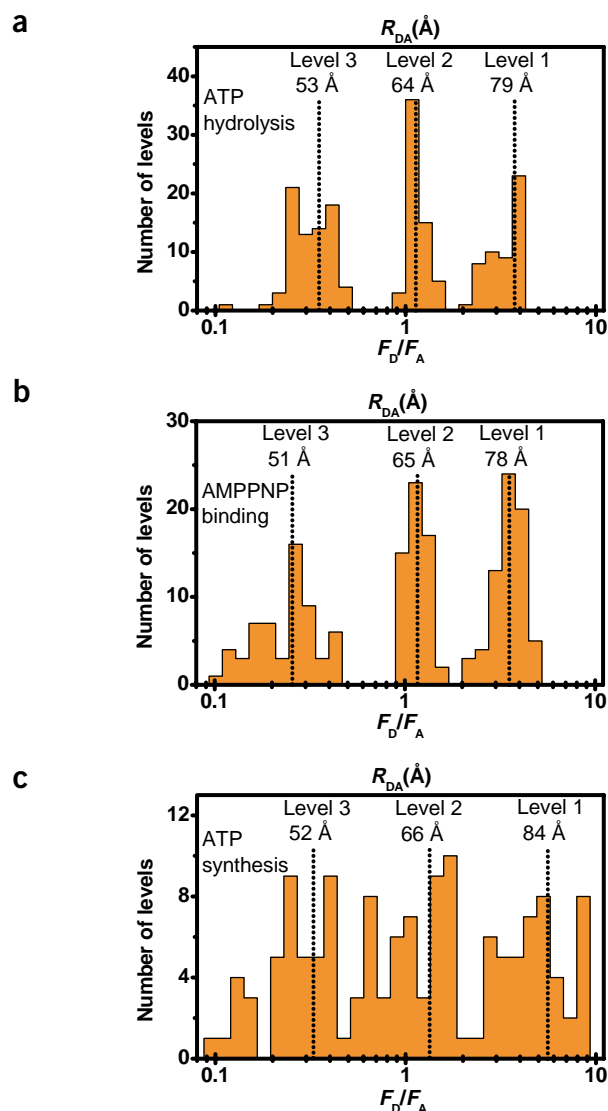

In addition, time traces of the fluorescence lifetime of the donor in the presence of the acceptor,  $\tau_{D(A)}$ , were simultaneously measured (Fig. 2b). Each  $F_D / F_A$  level corresponded to a well-defined  $\tau_{D(A)}$ : high FRET efficiencies (level 3, short distance) were characterized by a short  $\tau_{D(A)}$ , medium FRET efficiencies (level 2, medium distance) by a larger  $\tau_{D(A)}$ , and low FRET efficiencies (level 1, long distance) by high ratios of  $F_D / F_A$  and a long  $\tau_{D(A)}$ . The coincident steps in the levels of  $F_D / F_A$  and  $\tau_{D(A)}$  proved that these jumps were

caused by changes in FRET efficiencies and not by temporary photophysical effects<sup>25</sup> of the reporter dyes. FRET levels changed within a single photon burst during ATP hydrolysis in the order 1 $\rightarrow$ 3 $\rightarrow$ 2 $\rightarrow$ 1 (Fig. 2a) and 2 $\rightarrow$ 1 $\rightarrow$ 3 (Fig. 2b), respectively. By analyzing 222 traces of single  $F_0F_1$ -ATP synthases with two or more FRET levels, the predominant sequence of level transitions was found to be 1 $\rightarrow$ 3 $\rightarrow$ 2 $\rightarrow$ 1 $\rightarrow$ ... and so forth for >72% of the bursts. We conclude that during ATP hydrolysis at high ATP concentrations this interconversion of well-defined FRET levels clearly indicates a three-step rotary movement of the  $\gamma$  subunit in membrane-integrated  $F_0F_1$ -ATP synthase.

The fact that not all bursts exhibited the same sequence is due to the fast kinetics of ATP hydrolysis. In our analysis, only levels with duration of at least 5 ms were considered separate levels. From the average ATP turnover time and assuming an exponential distribution of the  $F_D / F_A$  level durations, we calculated a probability of 77% for levels that last for 5 ms or longer and thus are recognized as distinct levels during ATP hydrolysis. Therefore, apparently ‘wrong’ sequences were observed because short  $F_D / F_A$  levels were sometimes missed.

### Stepwise $\gamma$ -subunit rotation during ATP synthesis

To monitor subunit movements during ATP synthesis, we generated a transmembrane pH difference ( $\Delta$ pH) plus an additional electric potential difference ( $\Delta\phi$ ) across the liposome membrane<sup>19,20</sup> immediately before fluorescence measurements. In Figure 2c,d, typical photon bursts of TMR/Cy5bis- and Rh110/Cy5bis-labeled ATP synthases are shown (for additional traces see Supplementary Fig. 2c,d online). Three distinct FRET levels were identified within these photon bursts, characterized by constant  $F_D / F_A$  and  $\tau_{D(A)}$  levels, which interchange in coincident jumps to the next level. After mixing the two buffers in the microscopic flow chamber,  $\Delta$ pH and  $\Delta\phi$  with initial maximum values dissipated within 3–5 min, partly used by  $F_0F_1$ -ATP synthase for ATP synthesis and partly lost in a distinct process by proton leakage across the lipid membrane. Therefore, fluctuating FRET efficiencies within the photon bursts of liposome-embedded ATP synthase were observable only for the first few minutes. Several minutes after mixing, FRET states of  $F_0F_1$  remained constant within the bursts. Rarely, oscillations between two FRET states were detected.

**Figure 4** Histograms of the fluorescence intensity ratios  $F_D / F_A$  of single FRET-labeled  $F_0F_1$ . Top, most probable donor-acceptor distances,  $R'_{DA}$  (see Methods). (a) During ATP hydrolysis (1 mM ATP), 48 photon bursts with three or more steps (that is, 207 FRET level altogether) were analyzed. (b) Binding of AMPPNP (1 mM) with data from 185 photon bursts. (c) During ATP synthesis (100  $\mu$ M ADP, 5 mM phosphate, initial  $\Delta$ pH = 4.1), 32 photon bursts containing three or more steps (that is, 129 FRET level altogether) were analyzed.

In contrast to ATP hydrolysis, the order of level transitions was reversed for both pairs of FRET fluorophores. The observed sequences are 3 $\rightarrow$ 1 $\rightarrow$ 2 $\rightarrow$ 3 (Fig. 2c) and 1 $\rightarrow$ 2 $\rightarrow$ 3 $\rightarrow$ 1 (Fig. 2d), respectively. Repeating  $F_D / F_A$  and  $\tau_{D(A)}$  sequences in the direction 1 $\rightarrow$ 2 $\rightarrow$ 3 $\rightarrow$ 1 $\rightarrow$ ... were found for >83% of 188 analyzed bursts with two or more FRET levels. As the sequence of FRET levels is reversed, we conclude that the direction of  $\gamma$  rotation during ATP synthesis is opposite compared with that during ATP hydrolysis.

### Three AMPPNP-trapped $\gamma$ -subunit orientations

The existence of three distinct FRET levels was corroborated by an independent experiment. Upon addition of nonhydrolyzable adenosine-5'-( $\beta,\gamma$ -imido)triphosphate (AMPPNP) the enzyme was

expected to be trapped in one of three different orientations of the  $\gamma$  subunit with respect to the b subunits. In this case, the traces of single-particle events showed  $F_D / F_A$  levels that remained constant throughout each burst. The observation of three distinct FRET efficiencies upon addition of AMPPNP supports the proper discrimination of the anticipated  $\gamma$ -subunit orientations (Fig. 3a–c).

### Level histograms of the three FRET states

The statistical significance of the individual traces of  $F_0F_1$  was evaluated by the analysis of the FRET level histograms of ATP synthases during catalysis and AMPPNP binding (Fig. 4). We selected 48 photon bursts from single  $F_0F_1$  with three or more FRET levels during ATP hydrolysis. In the histogram of  $F_D / F_A$  levels (Fig. 4a), three peaks are clearly separated. In Figure 4b, the  $F_D / F_A$  level histogram in the presence of AMPPNP is shown. Three  $F_D / F_A$  levels are found also, with the center of the distribution of each level similar to those observed during ATP hydrolysis. At millimolar concentrations, ATP binds rapidly to the free nucleotide-binding site and the rate-limiting step is expected to be the release of ADP. The resting positions of the enzyme should therefore be the same as those after binding of AMPPNP, resulting in almost identical maxima of the  $F_D / F_A$  level histograms in the presence of ATP or AMPPNP.

The histogram of  $F_D / F_A$  levels, obtained from 32 photon bursts during ATP synthesis (Fig. 4c), shows again three subpopulations. When  $F_D / F_A$  level distributions are fitted with three Gaussians, the centers of the distributions are almost identical to those for ATP hydrolysis and AMPPNP binding. In the case of ATP synthesis, the maxima of the distribution were similar; however, the distributions were significantly broadened.

### Dwell times of the FRET states during catalysis

The durations of the different  $F_D / F_A$  levels during ATP hydrolysis and ATP synthesis were considered as dwell times of conformational states. A monoexponential fit to the level durations during ATP hydrolysis resulted in an average dwell time of 19 ms (Fig. 5a). This value agrees well with a turnover time of 15 ms for the hydrolysis of one ATP obtained from bulk experiments. For ATP synthesis, a monoexponential fit to the level durations yielded an average dwell time of 51 ms (Fig. 5b), in accordance with a turnover time of 43 ms for the synthesis of one ATP calculated from the initial rates in bulk experiments. This comparison indicates that the duration of the FRET states is directly correlated with the catalytic event.

### Fluorophore distances and $\gamma$ -subunit orientations

Single-molecule FRET data revealed additional structural information. From the homology model of  $F_0F_1$  (Fig. 1), the largest distance between the C $\alpha$  atoms of the amino acids b-Q64C and  $\gamma$ -T106C was estimated to be 73 Å. Rotation of the  $\gamma$  subunit by 120° and 240° resulted in two shorter distances in the range of 40–60 Å. According to the Förster theory of FRET<sup>26,27</sup>, two effects can influence  $F_D / F_A$  levels, donor-acceptor distances and orientations in transition dipole moments (factor  $\kappa^2$ ) of the donor relative to the acceptor dye. We calculated apparent donor-acceptor distances,  $R'_{DA}$ , from the measured fluorescence parameters. These apparent distances of 52, 65 and 80 Å (Fig. 4), representing mean values during catalysis and AMPPNP binding for the three FRET states within the enzyme, agree with estimates obtained from the model.

### DISCUSSION

We applied an intramolecular single-molecule FRET approach to show subunit rotation in the liposome-reconstituted holoenzyme  $F_0F_1$ -ATP

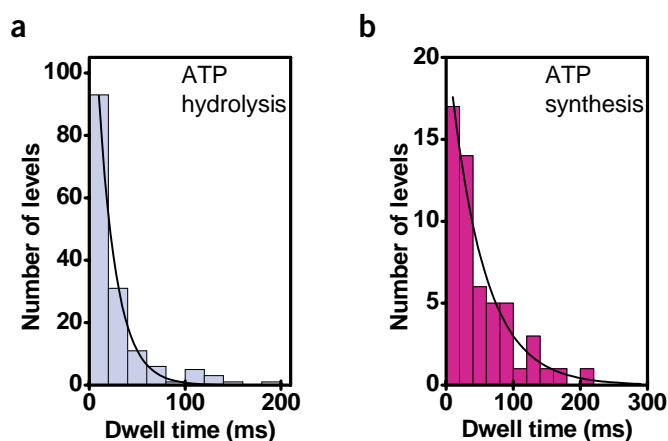

synthase powered by proton flow. Here, one fluorophore was attached to the rotating  $\gamma$  subunit of  $F_1$  and the other to the static, nonrotating b-subunit dimer of  $F_0$ . We achieved high-specificity labeling by separately labeling cysteines in  $F_1$  and  $F_0$  and subsequently reassembling and reconstituting the enzyme into liposomes. The FRET efficiency depends on the distance between the two fluorophores. Therefore, FRET efficiency changes between the two fluorophores at a single ATP synthase are expected to describe trajectories of the relative motion of the two labeled subunits during catalysis.

Upon addition of AMPPNP as a nonhydrolyzable substrate for the enzyme, we find three well-defined and distinct FRET levels and conclude that these levels correspond to three distances of the labeled residue 106 at a protruding part ('off-axis position') of the  $\gamma$  subunit with respect to the b subunits. The calculated ratio of corrected fluorescence intensities  $F_D / F_A$  between FRET donor and acceptor in the photon bursts of a single ATP synthase is independent of intensity fluctuations of the double-labeled enzyme on its transit pathway through the confocal detection volume. In addition to this intensity ratio, each FRET level is defined by a specific FRET donor fluorescence lifetime  $\tau_{(DA)}$ , and therefore, other photophysical causes effecting the quantum yields of the FRET fluorophores are unlikely. These stable FRET levels during a photon burst indicate the trapping of the  $\gamma$  subunit by AMPPNP in one of three distinguishable orientations. The three intramolecular distances calculated from the FRET efficiencies of these levels are in good agreement with the distances derived from our model of  $F_0F_1$ -ATP synthase and the expected positions of the  $\gamma$  subunit.

FRET-labeled ATP synthase in a freely diffusing liposome carries out proton transport-coupled ATP synthesis and hydrolysis almost undisturbed during real-time observation. The dwell times of the FRET levels correspond to the bulk rates of catalysis, during ATP hydrolysis as well as ATP synthesis, thereby independently excluding photophysical causes for interchanging FRET levels.

Given this direct correlation between FRET level and  $\gamma$ -subunit orientation,  $\gamma$ -subunit rotation in  $F_0F_1$ -ATP synthase occurs stepwise in both modes of catalysis and the direction of rotation during ATP synthesis is reversed compared with that during ATP hydrolysis. Using the actin-filament method, the rotation direction of the  $\gamma$  subunit in  $F_1$  subcomplexes during ATP hydrolysis has been determined to be counterclockwise when viewed from  $F_0$  (ref. 9). Therefore we attribute the FRET level sequence 1 $\rightarrow$ 3 $\rightarrow$ 2 $\rightarrow$ 1 $\rightarrow$ ... observed during ATP hydrolysis to the counterclockwise direction of rotation of the  $\gamma$  subunit (Fig. 1b). Stepwise rotation of the  $\gamma$  subunit during ATP hydrolysis has been discussed for  $F_1$ -ATPase<sup>10,11,28</sup> and for  $F_0F_1$ -ATP synthase<sup>18</sup> earlier and is confirmed here. In the present work, proton-driven ATP synthesis is also accompanied by a three-step rotary movement of the  $\gamma$  subunit and not by a quasi-continuous rotation, which might have been expected from the stoichiometry of at least nine translocated protons per 360° revolution and from the multistep rotational motion of the c subunits of  $F_0$  during ATP synthesis. These distinct distances between the FRET fluorophores remain constant throughout the dwell time of one  $\gamma$ -subunit orientation, before a consecutive 120° rotary movement of the  $\gamma$  subunit takes place, as has been shown unequivocally with immobilized  $F_1$  subcomplexes for the case of ATP hydrolysis at millimolar concentrations<sup>10</sup>. The mean stopping positions of the  $\gamma$  subunit upon ATP synthesis are similar to those observed in the AMPPNP-trapped states and those during ATP hydrolysis at millimolar ATP concentrations.

As anticipated in molecular dynamics simulations<sup>15,16</sup> and derived from theoretical considerations of microscopic reversibility, a reversed rotary motion of the  $\gamma$  subunit during ATP synthesis was predicted,

**Figure 5** Level duration distributions of FRET states. (a,b) Distributions during ATP hydrolysis (a) and ATP synthesis (b). Fits with monoexponential decay functions yield mean dwell times of 19 ms upon ATP hydrolysis and 51 ms upon ATP synthesis.

and is now strongly supported by our experiments. The rotary subunit movement is indicated by repeating sequences of three FRET levels, which are induced by distance changes between the FRET pair. In most cases, a consecutive order of the three  $\gamma$ -subunit orientations was observed, and in an opposite direction during ATP synthesis from that during ATP hydrolysis. Thus, unidirectional rotary motion of the  $\gamma$  subunit during both modes of catalysis seems very improbable. Any two-state model, including contracting-and-stretching modes of the  $\gamma$  subunit or back-and-forth swiveling modes between only two of the three catalytic sites, are not consistent with the repeating sequences of three FRET levels. Oscillations between two FRET states were rarely observed and can be attributed either to omitted levels or to an equilibrium state between a weak proton-motive force competing with the ATP hydrolysis backreaction.

The significant broadening of the three FRET levels during ATP synthesis allows us to predict the occurrence of substeps comparable to those observed in  $F_1$  subcomplexes during ATP hydrolysis. As first hints and as rare events we identified more than three FRET levels (substeps) in some photon bursts of  $F_0F_1$  during ATP synthesis. The origin of these substeps remains to be clarified. In principle, a hypothetical ADP-(plus  $P_i$ )-waiting state of the enzyme at one angular position of the  $\gamma$  subunit and a conformational state associated with the catalytic reaction or product release at another angular position can be discriminated by the dependence of substrate concentration. Detecting one ATP synthase in freely diffusing liposomes, as has been shown in this work, limits the observation time to several hundred milliseconds. Therefore, concentration dependencies must be studied by a modified approach, for instance with surface-immobilized liposomes using a streptavidin-biotin multilayer. Monitoring single enzymes at work under kinetic control in both directions of catalysis will reveal insights into the mechanism of the 'rotary nanomachine'  $F_0F_1$ -ATP synthase.

## METHODS

**FRET-labeled  $F_0F_1$ -ATP synthase from *E. coli*.**  $F_1$  of ATP synthase of *E. coli* carrying the cysteine mutation  $\gamma$ -T106C was prepared as described<sup>29</sup> using the plasmid pRA144 (ref. 30) expressed in strain RA1 (ref. 31). Specific stoichiometric labeling of the  $\gamma$  subunit was achieved with tetramethylrhodamine-maleimide (TMR, Molecular Probes) or Rhodamine110-maleimide (Rh110, Evotec) with labeling efficiencies between 50 and 60% (refs. 18,32).  $F_1$  with

$\gamma$ -T106C contains several buried cysteines<sup>33</sup>. However, at the given reaction conditions only  $\gamma$ -T106C is labeled<sup>32,33</sup>, as checked by fluorograms after SDS-PAGE.  $F_0F_1$ -ATP synthases of *E. coli* carrying the cysteine mutation b-Q64C were prepared separately<sup>19</sup> using the plasmid pRR76 (ref. 18) expressed in strain RA1. The cysteines of the b subunits were crosslinked with the cyanine dye Cy5-bis-C<sub>5</sub>-maleimide synthesized from (5-maleimidyl)-pentyl-1-amine and Cy5-bis-N-hydroxysuccinimidylester (bisreactive Cy5 NHS-ester obtained from Amersham Biosciences). Cy5-labeling efficiency of the b-subunit dimer was 64% with a yield of crosslinking of ~90%. The a and c subunits of  $F_0$  were not labeled as checked by fluorograms after SDS-PAGE. Cy5-labeled  $F_0F_1$  was reconstituted into liposomes (diameter ~100 nm),  $F_1$  was removed and Cy5-labeled  $F_0$  was reassembled with TMR- or Rh110-labeled  $F_1$  to yield the FRET-labeled  $F_0F_1$ -ATP synthase in liposomes, as described<sup>18</sup>. ATP synthesis rates were measured<sup>19,20</sup> at 23 °C, yielding  $v_S = 59 \pm 1 \text{ s}^{-1}$  for the nonlabeled b-mutant  $F_0$ -b64- $F_1$ ,  $v_S = 48 \pm 3 \text{ s}^{-1}$  for the labeled  $F_0$ -b64-Cy5- $F_1$ ,  $v_S = 24 \pm 2 \text{ s}^{-1}$  for the reassembled TMR-labeled  $F_0$ -b64- $F_1$ - $\gamma$ 106-TMR and  $v_S = 23 \pm 3 \text{ s}^{-1}$  for the FRET-labeled  $F_0$ -b64-Cy5- $F_1$ - $\gamma$ 106-TMR. ATP hydrolysis rates at 23 °C were  $v_H = 186 \pm 12 \text{ s}^{-1}$  for  $F_0$ -b64- $F_1$ ,  $v_H = 108 \pm 24 \text{ s}^{-1}$  for  $F_0$ -b64-Cy5- $F_1$  and  $v_S = 67 \pm 6 \text{ s}^{-1}$  for the reassembled and FRET-labeled  $F_0$ -b64-Cy5- $F_1$ - $\gamma$ 106-TMR. Reassembly causes slower rates<sup>18,21</sup>. All hydrolysis rates were inhibited by 40  $\mu\text{M}$  DCCD to remaining activities of  $6 \pm 4\%$ .

**Single-molecule FRET measurements.** Single-molecule FRET measurements were carried out as described<sup>18</sup> using continuous wave-excitation at 532 nm for TMR and pulsed excitation at 496 nm for Rh110. Confocal detection volumes of 6.8 fl for TMR/Cy5bis and 2.5 fl for Rh110/Cy5bis were used. Mean diffusion times through the confocal volume of 10–30 ms for the labeled  $F_0F_1$  in liposomes were determined by fluorescence correlation spectroscopy. Single-molecule fluorescence measurements under conditions of ATP hydrolysis (1 mM ATP) and AMPNP binding (1 mM AMPNP) were carried out in a buffer (pH 8) containing 20 mM succinic acid, 20 mM tricine, 2.5 mM  $\text{MgCl}_2$ , 80 mM NaCl and 0.6 mM KCl. ATP synthesis was measured after preincubation of the liposomes in 20 mM succinic acid buffer, pH 4.7, containing 5 mM  $\text{NaH}_2\text{PO}_4$ , 0.6 mM KOH, 2.5 mM  $\text{MgCl}_2$ , 100  $\mu\text{M}$  ADP, 20  $\mu\text{M}$  valinomycin. The transmembrane  $\Delta\text{pH}$  was generated by mixing the acidic liposomes with the basic buffer containing 200 mM tricine, pH 8.8, 5 mM  $\text{NaH}_2\text{PO}_4$ , 160 mM KOH, 2.5 mM  $\text{MgCl}_2$  and 100  $\mu\text{M}$  ADP in a T-shaped flow chamber with two syringes. This generated an initial transmembrane pH difference  $\Delta\text{pH} = 4.1$  with an additional electric potential difference  $\Delta\phi = 126 \text{ mV}$  (refs. 19,20). All samples of the double-labeled  $F_0F_1$  were diluted to a final concentration of ~90 pM.

**$F_0F_1$  identification in photon bursts.** Background count rates (usually between 0.5 and 2 kHz), obtained in each experiment from measurements of buffer solutions without labeled enzymes, were subtracted from the burst count rates. In addition, crosstalk (photons from the donor in the detection channel of the acceptor) and differences in the detection efficiencies of the donor and acceptor channels of the instrument were corrected, resulting in corrected fluorescence intensities for donor ( $F_D$ ) and acceptor ( $F_A$ ). A photon burst was considered 'significant' when the sum of photon counts in the donor and acceptor channel was >15 counts per ms. To eliminate events of remaining donor-labeled  $F_1$  that were not bound to  $F_0$  in liposomes, we excluded photon bursts with a duration <45 ms and, when Rh110 was used, with a donor anisotropy <0.12 (see Supplementary Fig. 1 online).

**Calculation of intramolecular FRET distances.** The reduced Förster radii<sup>25</sup>  $R_{0r} = 9,780 (J(\lambda) \kappa^2 n^{-4})^{1/6}$  for the FRET pairs TMR/Cy5bis and Rh110/Cy5bis were calculated using  $n = 1.33$  for the index of refraction and  $\kappa^2 = 2/3$ . The spectral overlap ( $J$ ) was determined from the respective donor emission and acceptor absorption spectra resulting in  $R_{0r} = 76 \text{ \AA}$  for TMR/Cy5bis and 55.5  $\text{Å}$  for Rh110/Cy5bis. Anisotropies of donor and acceptor were 0.2. Even in this case, it is still sufficient to assume  $\kappa^2 = 2/3$ , because our estimate for  $\kappa^2$  lies well in the range of possible  $\kappa^2$  values assuming the case of linear and planar (due to rotation) transition moments of donor and acceptor<sup>27</sup>. Based on these assumptions, it is appropriate to calculate apparent donor-acceptor distances,  $R'_{DA}$  from the measured fluorescence parameters using  $R'_{DA} = R_{0r} [\phi_A (F_D / F_A)]^{1/6}$ .

The apparent distances between donor and acceptor dyes were calculated from the maxima of the Gaussian distributions of  $F_D / F_A$  for the different levels. The effective acceptor fluorescence quantum yield in single-molecule experiments was  $\phi_A = 0.32$  for Cy5bis<sup>25</sup>. These distances are compared with geometrically estimated values from a model of  $F_0F_1$ . Therefore, homology alignment<sup>34</sup> of structures of the  $(\alpha_3\beta_3\gamma)$  subcomplex from the mitochondrial enzyme,  $\delta$ ,  $\epsilon$  plus  $\gamma$  and c subunits from X-ray<sup>3,35</sup> and NMR<sup>36,37</sup> analyses were combined with postulated structures of the  $c_{10}$ -ring<sup>8</sup> and a and b subunits<sup>38</sup> for an overview of intramolecular distances within  $F_0F_1$ -ATP synthase.

#### ACKNOWLEDGMENTS

This work is dedicated to the memory of K. Süss, who died on 17 March 2002. We thank R.H. Fillingame for his help with the b-mutants, R.A. Capaldi and R. Aggeler for the gift of the  $\gamma$ -mutant, O. Hucke for refinement of the  $F_0F_1$  model, and M. Antonik and E. Haustein for analytical software. We thank H. Grubmüller, R. Jahn, B.A. Melandri and P. Turina for critical reading the manuscript and helpful discussions and A. Börsch-Haubold for editorial suggestions. C.A.M.S. acknowledges financial support by the Bundesministerium für Bildung und Forschung (BioFuture grant 0311865).

#### COMPETING INTERESTS STATEMENT

The authors declare that they have no competing financial interests.

**Figure I:** Two-dimensional histogram of photon burst duration (i.e. diffusion time through the confocal detection volume) versus anisotropy  $r_D$  of the donor fluorophore (rhodamine 110) attached to the  $\gamma$ -subunit of  $F_0F_1$ -ATP synthase during ATP hydrolysis. The events resulting from the FRET-labeled holoenzyme incorporated in a liposome can be distinguished from unbound dye and remaining donor labeled  $F_1$  parts (not bound to  $F_0$ ) by their high  $r_D$ . The probability to observe a transition between two FRET levels within a photon burst depends on the duration of the event. Therefore, only photon bursts within the red shaded area are considered for further analysis (i.e. 382 bursts of 2127 bursts with  $r_D > 0.12$ ).

**Figure II:** Photon bursts of single FRET-labeled  $F_0F_1$ -ATP synthases in liposomes during ATP hydrolysis (**a**, **b**), and during ATP synthesis (**c**, **d**). FRET donor is TMR, FRET acceptor is Cy5bis in all traces. Corrected fluorescence intensity traces of the donor,  $F_D$ , and acceptor,  $F_A$ , are shown in green and red, respectively, corrected intensity ratios  $F_D/F_A$  are depicted in orange with a time window of 1 ms. Three distinct FRET levels are attributed (1, 2 or 3) at the top of the figures. Black horizontal lines indicate the mean FRET levels taken from the histogram, vertical lines mark beginning and end of a level. In trace (**b**), the enzyme exhibits short dwell times for a FRET level, i.e. fast ATP turnover is depicted. In trace (**d**), photophysical fluorophore blinking after 340 ms interrupts the detection of FRET states for approximately 100 ms before ongoing ATP synthesis is demonstrated by interchanging FRET levels.
